1   Neural Networks and Deep Learning

1.1   Introduction to Deep Learning

- Takes input x to a "neuron" and gives some output y

- Simple neural network has a single input, neuron and output
- x: size of the house
- y: price of the house
- Hypothesis (blue line) is a ReLU (Rectified Linear Unit)

- More complex neural networks can be formed by "stacking" neurons

- Every input layer feature is interconnected with every hidden layer feature
  - The neural network will decide what the intermediate features will be
- Most useful in supervised learning settings

1.1.1 Supervised Learning

- Aims to learn a function to map an input x to an output y
    - Real estate: predicting house prices from the house features
    - Online advertising: showing ads based on probability of user clicking on ad
    - Photo tagging: tagging images based on objects in the image
    - Speech recognition: generating a text transcript from audio
    - Machine translation: translating from one language to another
    - Autonomous driving: returning the positions of other cars from images and radar info
- Different types of neural network used for different tasks
    - Standard neural network: real estate and online advertising
    - Convolutional neural network (CNN): image data
    - Recurrent neural network (RNN): audio and language data (sequenced data)
    - Hybrid neural network: Autonomous driving (more complex input)

Standard NN   Convolutional NN   Recurrent NN

- Supervised learning can be applied to structured and unstructured data
    - Structured data has features with well defined meanings
    - Unstructured data has more abstract features (images, audio, text)

- Deep learning has only recently started to become more widespread
    - Given large amounts of data and a large NN, deep learning will outperform more traditional learning algorithms
    - For small amounts of data, any performance of the algorithm depends on specific implementation
- "Scale drives deep learning progress"
    - Both the scale of the data and the NN
- Recent algorithmic innovations with increase scale of computation

- Idea to switch from sigmoid activation function to ReLu function increased NN performance
- Ends of sigmoid function have close to 0 gradient so and therefore result in small changes in θ
- ReLu function has gradient of 1 for positive values

- Neural network process is iterative
  - Increasing speed at which a NN can be trained allows different ideas to be tried

1.2 Neural Network Basics

1.2.1 Logistic Regression as a Neural Network

- Logistic regression used for binary classification
- For a colour image, of 64×64 pixels, will have total 12288 input features
  - Image is stored as 3 separate matrices for each colour channel
  - All pixel intensities should be unrolled into a single feature vector

$$n = 12288$$

$$x \in \mathbb{R}^{12288}$$

  - For a matrix X of shape (a, b, c, d), want a matrix X_flatten of shape $(b * c * d, 1)$

```
X_flatten = X.reshape(X.shape[0], -1).T
```

Notation

$$\{(x^{(1)}, y^{(1)}), (x^{(2)}, y^{(2)}), ..., (x^{(m)}, y^{(m)})\}$$

- (x, y): single training example
  - $x \in \mathbb{R}^{n_x}$ (n_x = number of features)
  - $y \in \{0, 1\}$

4

- $(x^{(i)}, y^{(i)})$: i^{th} training example
- $m = m_{train}$
- $m_{test} = \#$ of test examples
- $X = \begin{bmatrix} | & | & & | \\ x^{(1)} & x^{(2)} & ... & x^{(3)} \\ | & | & & | \end{bmatrix}$
  - $X \in \mathbb{R}^{n_x \times n}$
- $Y = \begin{bmatrix} y^{(1)} & y^{(2)} & ... & y^{(m)} \end{bmatrix}$
  - $Y \in \mathbb{R}^{1 \times m}$

Logistic Regression

- Given x, want $\hat{y} = P(y = 1 | x)$
  - Since $\hat{y}$ is a probability, want $0 \le \hat{y} \le 1$
- Parameters: $w \in \mathbb{R}^{n_x}, b \in \mathbb{R}$
- Output: $\hat{y} = \sigma(w^T x + b)$

$$\sigma(z) = \frac{1}{1 + e^{-z}}$$

$$z = w^T x + b$$

- Aim is to learn parameters w and b such that $\hat{y}$ is a good estimate of the probability
- Previous convention had θ vector with an additional θ_0 parameter
  - Keeping θ_0 (b) separate from the rest of the parameters is easier to implement

Cost Function

- Given $\{(x^{(1)}, y^{(1)}), (x^{(2)}, y^{(2)}), ..., (x^{(m)}, y^{(m)})\}$, want $\hat{y}^{(i)} \approx y^{(i)}$
- Squared error function not used for logistic regression loss function

– Optimization problem becomes non convex and will have local optima

$$\mathcal{L}(\hat{y}, y) = -(y\log(\hat{y}) + (1 - y)\log(1 - \hat{y}))$$

- If $y = 1$:
    - $\mathcal{L}(\hat{y}, y) = -\log(\hat{y})$
    - Want large $\log(\hat{y})$ $\therefore$ want large $\hat{y}$
    - $\hat{y}$ has a max of 1 $\therefore$ want $\hat{y} = 1$
- If $y = 0$:
    - $\mathcal{L}(\hat{y}, y) = -log(1 - \hat{y})$
    - Want large $\log(1 - \hat{y})$ $\therefore$ want small $\hat{y}$
    - $\hat{y}$ has a min of 0 $\therefore$ want $\hat{y} = 0$
- Cost function:

$$J(w, b) = \frac{1}{m}\sum_{i=1}^{m}\mathcal{L}(\hat{y}^{(i)}, y^{(i)})$$

$$= -\frac{1}{m}\sum_{i=1}^{m}[y^{(i)}\log(\hat{y}^{(i)}) + (1 - y^{(i)})\log(1 - \hat{y}^{(i)})]$$

- Average loss function over all training examples

Gradient Descent
- Want to find values of w and b that minimize the cost function $J(w, b)$
    - For logistic regression, w and b usually initialized to 0
- One iteration of gradient descent will take a step in the direction of steepest descent

```
Repeat {
    w  :=  w  -  α ∂J(w,b)/∂w
    b  :=  b  -  α ∂J(w,b)/∂b
}
```

- Using the computation graph:

$$\frac{\partial \mathcal{L}(a, y)}{\partial a} = -\frac{y}{a} + \frac{1 - y}{1 - a}$$

$$\frac{\partial \mathcal{L}(a, y)}{\partial z} = \frac{\partial \mathcal{L}}{\partial a} \times \frac{\partial a}{\partial z}$$

$$= (-\frac{y}{a} + \frac{1-y}{1-a}) \times a(1-a)$$

$$= a - y$$

$$\frac{\partial \mathcal{L}}{\partial w_1} = x_1 \times \frac{\partial \mathcal{L}}{\partial z}$$

$$\frac{\partial \mathcal{L}}{\partial w_2} = x_2 \times \frac{\partial \mathcal{L}}{\partial z}$$

$$\frac{\partial \mathcal{L}}{\partial b} = \frac{\partial \mathcal{L}}{\partial z}$$

- Partial derivative over all training examples calculated by taking the average `dw1`

$$\frac{\partial}{\partial w_1} J(w, b) = \frac{1}{m} \sum_{i=1}^{m} \frac{\partial}{\partial w_1} \mathcal{L}(a^{(i)}, y^{(i)})$$

Initialize J = 0, dw1 = 0, dw2 = 0, db = 0

```
For i = 1 to m:
    z^(i) = w^T x^(i) + b
    a^(i) = σ(z^(i))

    J += -[y^(i) log(a^(i)) + (1-y^(i))log(1-a^(i))]
    dz^(i) = a^(i) - y^(i)
    dw1 += x_1^(i) dz^(i)
    dw2 += x_2^(i) dz^(i)
    db += dz^(i)

J /= m
dw1 /= m
dw2 /= m
db /= m

w1 := w1 - α dw1
w2 := w2 - α dw2
b := b - α db
```

- Above implementation requires `for` loop over all features for all training examples
    - Vectorization can be used to remove explicit `for` loops
    - Vectorization required for deep learning to be efficient

1.2.2 Vectorisation in Python

- Deep learning performs best on large data sets
    - Code must be able to run quickly to be effective on large data sets

$$z = w^T x + b$$

$$w \in \mathbb{R}^{n_x} \quad x \in \mathbb{R}^{n_x}$$

- Non vectorized implementation:

```
z = 0
for i in range(n_x):
    z += w[i] * x[i]
z += b
```

- GPUs and CPUs both have parallelization instructions (SIMD: Single Instruction Multiple Data)
    - If built in functions are used, `numpy` will use parallelism to perform computations faster

- For logistic regression, need to calculate z and a values for each training example

$$z^{(i)} = w^T x^{(i)} + b$$

$$a^{(i)} = \sigma(z^{(i)})$$

$$X = \begin{bmatrix} | & | & & | \\ x^{(1)} & x^{(2)} & ... & x^{(m)} \\ | & | & & | \end{bmatrix}$$

$$w \in \mathbb{R}^{n_x} \quad X \in \mathbb{R}^{n_x \times m}$$

$$\begin{bmatrix} z^{(1)} & z^{(2)} & ... & z^{(m)} \end{bmatrix} = w^T X + \begin{bmatrix} b & b & ... & b \end{bmatrix}$$
$$= \begin{bmatrix} w^T x^{(1)} + b & w^T x^{(2)} + b & ... & w^T x^{(m)} + b \end{bmatrix}$$

- In Python:

```
Z = np.dot(w.T, X) + b
```

– Python will broadcast the value `b` so it can be added to the matrix

• Vectorized implementation of sigmoid function can be used on `Z` to calculate `A`

$$A = \begin{bmatrix} a^{(1)} & a^{(2)} & ... & a^{(m)} \end{bmatrix}$$

$$dz^{(i)} = a^{(i)} - y^{(i)}$$

$$dz = A - Y$$

$$db = \frac{1}{m} \sum_{i=1}^{m} dz^{(i)}$$
$$dw = \frac{1}{m} X (dz)^T$$

```
Z = np.dot(w.T,X) + b
A = sigmoid(Z)
dz = A - Y
dw = 1/m * np.dot(X, dz.T)
db = 1/m * np.sum(dz)

# Gradient descent update
w = w - alpha * dw
b = b - alpha * db
```

• `for` loop is required to run multiple iterations of gradient descent

1.3   Shallow Neural Networks

• A neural network will have stacked logistic regression units in each layer
    – Logistic regression output from one layer will be fed to another layer

9

- Input layer of the neural network contains the feature x_1, x_2, x_3
    - $a^{[0]} = X$
- Intermediate layers in the network are hidden layers
    - Hidden layers do not have "true" values in the training set
- Final layer in the network is the output layer
    - Generates the predicted value $\hat{y}$
- Above diagram is a 2 layer NN
    - Input layer is layer 0
- Each layer will have parameters w and b associated with them
- Each node in the NN will perform logistic regression with its inputs

$$z_i^{[l]} = w_i^{[l]T}x + b_i^{[l]} \quad \rightarrow \quad a_i^{[l]} = \sigma(z_i^{[l]})$$

$$W^{[1]} = \begin{bmatrix} - & w_1^{[1]T} & - \\ - & w_2^{[1]T} & - \\ - & w_3^{[1]T} & - \\ - & w_4^{[1]T} & - \end{bmatrix}$$

$$a^{[0]} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}$$

$$b^{[1]} = \begin{bmatrix} b_1^{[1]} \\ b_2^{[1]} \\ b_3^{[1]} \\ b_4^{[1]} \end{bmatrix}$$

$$z^{[1]} = \begin{bmatrix} z_1^{[1]} \\ z_2^{[1]} \\ z_3^{[1]} \\ z_4^{[1]} \end{bmatrix}$$

$$= \begin{bmatrix} w_1^{[1]T} a^{[0]} + b_1^{[1]} \\ w_2^{[1]T} a^{[0]} + b_1^{[1]} \\ w_3^{[1]T} a^{[0]} + b_1^{[1]} \\ w_4^{[1]T} a^{[0]} + b_1^{[1]} \end{bmatrix}$$

$$= w^{[1]} a^{[0]} + b^{[1]}$$

$$a^{[1]} = \begin{bmatrix} a_1^{[1]} \\ a_2^{[1]} \\ a_3^{[1]} \\ a_4^{[1]} \end{bmatrix}$$

$$= \sigma(z^{[1]})$$

$$z^{[2]} = W^{[2]} a^{[1]} + b^{[2]} \quad \rightarrow \quad a^{[2]} = \sigma(z^{[2]})$$

- Vectorized method should be able to work on all training examples at one time
    - Vector for each training example can be stacked horizontally in a matrix
    - Vertical dimension will be the number of units in a layer (n_x for the input layer)

$$X = \begin{bmatrix} | & | & & | \\ x^{(1)} & x^{(2)} & & x^{(m)} \\ | & | & & | \end{bmatrix}$$

$$Z^{[1]} = \begin{bmatrix} | & | & & | \\ z^{[1](1)} & z^{[1](2)} & ... & z^{[1](m)} \\ | & | & & | \end{bmatrix}$$

$$A^{[1]} = \begin{bmatrix} | & | & & | \\ a^{[1](1)} & a^{[1](2)} & ... & a^{[1](m)} \\ | & | & & | \end{bmatrix}$$

$$Z^{[1]} = W^{[1]} X + b^{[1]}$$
$$A^{[1]} = \sigma(Z^{[1]})$$
$$Z^{[2]} = W^{[2]} A^{[1]} + b^{[2]}$$
$$A^{[2]} = \sigma(Z^{[2]})$$

11

1.3.1   Activation Functions

- After z values are calculated, activation function must be run to get the activation value a

$$a_{sigmoid} = \frac{1}{1 + e^{-z}}$$

- Alternatively $a^{[1]} = g(z^{[1]})$ where g is a non linear function
- tanh function almost always performs better than the sigmoid function
    - Equivalent to a transformed version of the sigmoid function
    - tanh function is odd and is "centered" around the origin
    - The mean of the data will be closer to 0 and will help with learning in the next layer

$$a_{\text{tanh}} = \frac{e^z - e^{-z}}{e^z + e^{-z}}$$
- For binary classification, the final output layer can use the sigmoid function
    - Want the value of $\hat{y}$ to be between 0 and 1
- For both the sigmoid and tanh functions, when z is large, the gradient is very small
    - Results in a slower gradient descent
- ReLU function has a gradient of 1 when z is positive
– Gradient is 0 when z is negative

- For majority of the ReLU function, gradient is very different from 0
    – Will typically allow NN to learn much faster than sigmoid or tanh function
- ReLU function should be used as the default activation function
- The leaky ReLu function has a slight positive gradient when z is negative

$$a_{leakyReLU} = \max(0.01z, z)$$

- For a NN to compute more complex functions, activation function must be non linear
    – If a linear activation function is used, final output of the NN can only be a linear function
    – Multiple linear activation neurons with a sigmoid as the output neuron is equivalent to standard logistic regression
- Linear activation function can be used in the output layer if output is a real number
- Derivative of the activation function must be calculated for backpropagation
    – Sigmoid function

$$g(z) = \frac{1}{1 + e^{-z}}$$

$$\frac{d}{dz}g(z) = \frac{1}{1 + e^{-z}}\left(1 - \frac{1}{1 + e^{-z}}\right)$$
$$= g(z)(1 - g(z))$$

    – tanh function

$$g(z) = \tanh(z)$$
$$= \frac{e^z - e^{-z}}{e^z + e^{-z}}$$

$$\frac{d}{dz}g(z) = 1 - \left(\frac{e^z - e^{-z}}{e^z + e^{-z}}\right)^2$$
$$= 1 - g(z)^2$$

- ReLU function

$$g(z) = \max(0, z)$$
$$\frac{d}{dz}g(z) = \begin{cases} 0 & \text{if } z < 0 \\ 1 & \text{if } z \geq 0 \end{cases}$$

- Leaky ReLU function

$$g(z) = \max(0.01z, z)$$
$$\frac{d}{dz}g(z) = \begin{cases} 0.01 & \text{if } z < 0 \\ 1 & \text{if } z \geq 0 \end{cases}$$

1.3.2 Gradient Descent for Neural Networks

- For a single hidden layer NN, parameters are: $w^{[1]}, b^{[1]}, w^{[2]}, b^{[2]}$
  - $w^{[1]} \in \mathbb{R}^{n_1 \times n_0}$
  - $b^{[1]} \in \mathbb{R}^{n_1 \times 1}$
  - $w^{[2]} \in \mathbb{R}^{n_2 \times n_1}$
  - $b^{[2]} \in \mathbb{R}^{n_2 \times 1}$

- Cost function: $J(w^{[1]}, b^{[1]}, w^{[2]}, b^{[2]}) = \frac{1}{m}\sum_{i=1}^{n}\mathcal{L}(\hat{y}, y)$

- For one iteration of gradient descent:

$$w^{[1]} := w^{[1]} - \alpha dw^{[1]}, \; b^{[1]} := b^{[1]} - \alpha db^{[1]}$$

$$w^{[2]} := w^{[2]} - \alpha dw^{[2]}, \; b^{[2]} := b^{[2]} - \alpha db^{[2]}$$

  - Gradient descent step will take place after backpropagation calculates the derivatives

- Forward propagation:

$$Z^{[1]} = W^{[1]}X + b^{[1]}$$
$$A^{[1]} = g^{[1]}(Z^{[1]})$$
$$Z^{[2]} = W^{[2]}A^{[1]} + b^{[2]}$$
$$A^{[2]} = g^{[2]}(Z^{[2]})$$

- Backpropagation:

$$dz^{[2]} = A^{[2]} - Y$$
$$dw^{[2]} = \frac{1}{m} dz^{[2]} A^{[1]T}$$
$$db^{[2]} = \frac{1}{m}\texttt{np.sum}(dz^{[2]}, \texttt{axis = 1, keepdims = True})$$
$$dz^{[1]} = w^{[2]T} dz^{[2]} \times g^{[1]'}(z^{[1]})$$
$$dw^{[1]} = \frac{1}{m} dz^{[1]} X^T$$
$$db^{[1]} = \frac{1}{m}\texttt{np.sum}(dz^{[1]}, \texttt{axis = 1, keepdims = True})$$

1.3.3 Random Initialization

- Weights must be initialized randomly for a NN
  - Weights can be initialized to 0 for logistic regression
  - The bias terms b can be initialized
- If weights are initialized to 0, all neurons in a layer will compute the same hypothesis

```
W1 = np.random.randn((2,2)) * 0.01
b1 = np.zero((2,1))
```

- Weights should be initialized to small random values
  - If weight is too large, activation value $z^{[1]}$ will be large
  - If sigmoid or tanh function is used, derivative will be very small and learning will be very slow
- Different constant for `np.random.randn` should be used for deeper neural networks

1.4 Deep Neural Networks

- Logistic regression is equivalent to a 1-layer NN
- Deep NN have more hidden layers
  - Number of hidden layers in the network can be a parameter for the ML problem

- – Above network has 4 layers, $L = 4$
- – $n^{[l]} =$ number of units in layer l
- – $a^{[l]} =$ activations in layer l
- The inputs x are the activations of the first layer, $x = a^{[0]}$
  - – Prediction $\hat{y}$ will be the activations of the last layer, $\hat{y} = a^{[L]}$
- Forward propagation for a deep NN will follow the same pattern for all layers

$$z^{[l]} = w^{[l]}a^{[l-1]} + b^{[l]}$$

$$a^{[l]} = g^{[l]}(z^{[l]})$$

- For a vectorized implementation

$$Z^{[l]} = W^{[l]}A^{[l-1]} + b^{[l]}$$

$$A^{[l]} = g^{[l]}(z^{[l]})$$

  - – Explicit for loop will be used to loop over the layers in the network
  - – b will still be a column vector but will apply correctly due to broadcasting
  - – When working with W and A matrices, A will be for the previous layer so the dimensions will fit
- When debugging NN, can look at dimensions of all the matrices
- For a non vectorized implementation:
  - – $W^{[l]} : (n^{[l]}, n^{[l-1]})$
  - – $b^{[l]} : (n^{[l]}, 1)$
  - – Dimensions of dw and db should be the same as the dimensions of W and b
  - – $a^{[l]}, z^{[l]} : (n^{[l]}, 1)$
- For a vectorized implementation, z vectors and a vectors will be stacked horizontally for all training examples

- $Z^{[l]}, A^{[l]} : (n^{[l]}, m)$

- Deep NN tend to work better as each layer can compute increasingly complex functions
  - Face recognition: edge detection → individual features → large parts of the face
  - Audio: low level waveforms → phonemes → words → sentences

- Functions that can be computed with a "small" deep neural network require exponentially more hidden units in a shallower network

- For each forward propagation step, the value of $z^{[l]}$ should be cached for backpropagation
  - Values of $w^{[l]}$ and $b^{[l]}$ can also be stored in the cache so they can be accessed for backpropagation

- All forward propagation steps will carried out until the hypothesis, $\hat{y}$ is found
  - Using cached values, all backpropagation steps will be carried out until $dz^{[1]}$
  - Parameters $W^{[l]}$ and $b^{[l]}$ can be updated accordingly

$$W^{[l]} := W^{[l]} - \alpha dw^{[l]}$$

$$b^{[l]} := b^{[l]} - \alpha db^{[l]}$$

- Backpropagation will also follow a pattern for all layers in the NN
  - $dz^{[l]} = da^{[l]} * g^{[l]'}(z^{[l]})$
  - $dW^{[l]} = dz^{[l]} a^{[l-1]T}$

- $db^{[l]} = dz^{[l]}$
- $da^{[l-1]} = W^{[l]T} dz^{[l]}$

- For a vectorized implementation:
  - $dZ^{[l]} = dA^{[l]} * g^{[l]'}(Z^{[l]})$
  - $dW^{[l]} = \frac{1}{m} dZ^{[l]} A^{[l-1]T}$
  - $db^{[l]} = \frac{1}{m}$np.sum($dZ^{[l]}$, axis=1, keepdims=True)
  - $dA^{[l-1]} = W^{[l]T} dZ^{[l]}$

1.4.1 Parameters vs Hyperparameters

- Parameters of the NN are the W and b matrices
- NN also has a number of associated hyperparameters:
  - Learning rate α
  - Number of iterations z''
  - Number of layers in the network
  - Number of hidden units
  - Choice of activation function
- Hyperparameters will control the values of W and b
- Deep learning has many more hyperparameters than earlier eras of machine learning
  - Applying deep learning becomes an empirical process
- Intuitions about hyperparameters may be different across different applications

2 Improving Deep Neural Networks: Hyperparameter Tuning, Regularization and Optimization

2.1 Practical Aspects of Deep Learning

- Applying ML is a highly iterative process
  - Very hard to choose "correct" values for hyperparameters
- Deep learning used in many different areas
  - NLP
  - Computer vision
  - Speech analysis
  - Structured data
    * Advertisement
    * Search engines
    * Computer security
    * Logistics
- Intuitions from one subject area often don't transfer to another application
- Success of deep learning can depend on speed of iteration
  - Choice of split of the data can influence speed of iteration
- Whole dataset should be split into training, development and test set
  - Dev set should be used rate performance of different models
  - Final model should be evaluated on the test set
  - Split will allow better evaluation of bias and variance of the model
- Previous eras of ML had a 60/20/20 split between dataset

- For the big data era, a smaller percentage of data is given to the dev and test sets
  - For 1,000,000 examples, can allocate just 10,000 examples each to dev and test set
  - 10,000 examples is enough to run the algorithm and get a good idea about the algorithm performance
- Recent trends also show mismatched training and test set distributions
  - For images, training set may have very high quality images while test set may have lower quality
  - Dev and test set should come from the same distribution
- Dataset might be split to not include a test set
  - Dev set can be used to get to a "good" model
  - Since data is fit to the dev set, there is no unbiased estimate of performance
  - When data doesn't include a test set, dev set is usually referred to as "test" set
  - Resulting model may overfit to the dev set

2.1.1 Bias and Variance

- In the deep learning era, there tends to be less of a discussion about the bias/variance trade off
- In 2 dimensions, data can be plotted to look for high bias or variance
  - High bias classifiers underfit the data
  - High variance classifiers overfit the data
- For higher dimensions, training set error and dev set error can be used
  - High variance classifier has low training error and high dev set error
  - High bias classifier has high training error and high dev set error
  - Classifier with high bias and high variance will have high training error and even higher dev set error
- Above ideas only work with the assumption that the optimal error is 0%
  - Training and dev set must also come from the same distribution

2.1.2 Basic Recipe for Machine Learning

- Train initial algorithm and reduce bias of algorithm to an "acceptable value"
  - Use a larger network
  - Train algorithm for longer

- Reduce variance of the algorithm by getting more data
    - Add regularization terms to the cost function
- Bias and variance can also be reduced by using a more appropriate NN architecture
- In the big data era, bias and variance can be reduced without affecting each other
    - Training a bigger network typically reduce the bias
    - Getting more training data will typically reduce the variance
- Using regularization will have a bias variance trade off

2.1.3 Regularization

- Adding regularization will usually help in reducing variance and prevent overfitting
    - Regularization will only affect how the weights change during backpropagation
    - For forward propagation, regularization has no effect
- For logistic regression:

$$J(w, b) = \frac{1}{m} \sum_{i=1}^{m} \mathcal{L}(\hat{y}^{(i)}, y^{(i)}) + \frac{\lambda}{2m} ||w||_2^2$$

$$||w||_2^2 = \sum_{j=1}^{n_x} w_j^2$$
$$= w^T w$$

    - Above method is L_2 regularization after the L_2 norm (Euclidean norm) of w
    - b values can also be regularized but will have a much smaller effect than w
- L_1 regularization adds the term:

$$\frac{\lambda}{m} \sum_{i=1}^{n_x} |w| = \frac{\lambda}{m} ||w||_1$$

    - Using L_1 regularization will result in w being sparse
    - Can be seen to compressing the model
- L_2 regularization is more common for deep learning
- Regularization parameter λ will be set using the cross validation set
    - `lambda` is a reserved keyword in Python

- For a neural network:

$$J(w^{[1]}, b^{[1]}, ..., w^{[l]}, b^{[l]}) = \frac{1}{m}\sum_{i=1}^{m}\mathcal{L}(\hat{y}^{(i)}, y^{(i)}) + \frac{\lambda}{2m}\sum_{l=1}^{L}||w^{[l]}||^2$$

$$||w^{[L]}||^2 = \sum_{i=1}^{n^{[l]}}\sum_{j=1}^{n^{[l-1]}}(w_{i,j}^{[l]})^2$$

  - $||W^{[l]}||_F^2$ known as the Frobenius norm of the matrix
- Since new term added to cost function, $\frac{\partial J}{\partial W^{[l]}}$ will be different

$$dW^{[l]} = ... + \frac{\lambda}{m}W^{[l]}$$

$$W^{[l]} = W^{[l]} - \frac{\alpha\lambda}{m}W^{[l]} - \alpha(...)$$

  - Also known as weight decay as value of W will decrease on every iteration

$$W^{[l]} - \frac{\alpha\lambda}{m}W^{[l]} = \left(1 - \frac{\alpha\lambda}{m}\right)W^{[l]}$$

  - Value of $\left(1 - \frac{\alpha\lambda}{m}\right)$ will be slightly less than 1
- Adding regularization term will penalize the weight matrix from being too large
  - As the value of λ is increased, the weights in w will get closer to 0
  - Each hidden unit will have a smaller effect and the resulting NN will be simpler
- When using the tanh function, penalizing w will make $z^{[l]}$ smaller
  - For a small $z^{[l]}$, tanh function is roughly linear
  - If all hidden units in the network are roughly linear, the result of the NN will also be roughly linear

Dropout Regularization
- Each layer in the NN has a probability of eliminating a node
  - When a node is eliminated, all outgoing links from the node are also deleted
  - Each example will be trained on a smaller network so will have less chance of overfitting
- For each different training example, the NN is reset and randomly eliminates nodes again
- Inverted dropout:

```
    d3 = np.random.rand(a3.shape[0], a3.shape[1]) < keep_prob
    a3 = np.multiply(a3, d3)
    a3 /= keep_prob
```

- For `keep_prob` = 0.8 each node has a 0.2 chance of being removed
- Activation values should be scaled by `keep_prob` so the expected value of z can stay constant
- On each pass through the training set, a different set of units should be zeroed out

- At test time, dropout should not be used as it will create noise in the predictions
- A single hidden unit cannot rely on a specific feature as it may not be used on each iteration

  - Weights for the unit will be spread out between the units
  - Has the same effect as shrinking the weights like L2 regularization
  - The equivalent L2 penalty on different weights depends on the size of the activations being used for the weight

- `keep_prob` can be varied between the layers

  - Larger layers may be more prone to overfitting and can have a larger `keep_prob`
  - For small layers with a very small chance of overfitting, `keep_prob` can be set to 1

- Many dropout implementations started with computer vision

  - Input size for computer vision is extremely large

- Cost function is not well defined when dropout is used

  - Can set `keep_prob` to 1 and check for monotonically decreasing J
  - When J is decreasing, then can reduce the value of `keep_prob` to use dropout

Other Regularization Methods

- Getting more training data will almost always help overfitting

  - May not be possible to get more training data or very expensive

- Data augmentation will create new examples and can help reduce overfitting
- For an image dataset:

  - Flipping the image horizontally

- Randomly cropping and distorting the image
- Magnitude of image transformation depends on classifier
  - For a cat dataset, image should not be flipped vertically
  - For OCR, distortions and rotations can be slightly more extreme

- Early stopping can be used to prevent overfitting from happening
  - If the NN is overfitting the data, the dev set error will initially decrease before increasing
  - Training of the NN can be stopped when the dev set error is lowest and the data has not been overfit
- Using early stopping links the task of optimizing J and not overfitting the data
  - Early stopping will prevent the cost function from being optimized
- L2 regularization is a better method to prevent overfitting
  - Requires a choice for the value of λ and is much more computationally expensive

2.1.4 Setting up the Optimization Problem

- Normalization can be used to speed up the training of a NN
  - Subtract the mean:
    $$\mu = \frac{1}{m} \sum_{i=1}^{m} x^{(i)}$$
 $$x := x = \mu$$

  - Normalize the variance:
    $$\sigma^2 = \frac{1}{m} \sum_{i=1}^{m} x^{(i)} **2$$
    $$x/ = \sigma$$

- When normalizing a training set, test set and training set should be processed together

– All the data must go through the same transformation

- For data that is not normalized, the cost function will be very elongated
  – The gradient will be quite shallow and will take longer to converge
  – Algorithm will require a smaller learning rate
- On average, normalized data will have a cost function that is more symmetric
  – Gradient descent will converge faster and can use a larger learning rate
Vanishing/Exploding Gradients

- For very deep neural networks, the derivatives can get exponentially big or small
- If the weights of a NN are all the same, the prediction $\hat{y}$ will x to the Lth power
  – For $W^{[l]} > I$ the gradient will explode
  – For $W^{[l]} < I$ the gradient will vanish

- Some modern applications use 152 layer NN
    - Require careful initialization of the weights to ensure correct training
- For a single neuron:
    - The output $\hat{y}$ will be the sum of all $w_i x_i$

$$z = w_1 x_1 + w_2 x_2 + ... + w_n x_n$$

    - For a large n, want a smaller w_i
    - Want $\text{Var}(w_i) = \frac{1}{n}$

$W^{[l]}$ = `np.random.randn(shape)` $*$ `np.sqrt`$\left(\frac{1}{n^{[l-1]}}\right)$

    - Variance of Gaussian random variable can be set by multiplying by sqrt tem
- For ReLU activation function, the variance should be set to $\frac{2}{n}$
    - tanh activation uses Xavier initialization $\frac{1}{n^{[l-1]}}$
    - Yoshua Bengio multiplied random variable by $\sqrt{\frac{2}{n^{[l-1]}+n^{[l]}}}$
- Initialization of weights aims to set weight matrices close to 1
    - Helps to prevent $\hat{y}$ from vanishing or exploding too quickly
- Variance parameter can be tuned as another hyperparameter

Gradient Checking

- Can be used to ensure implementation of backpropagation is correct
- Requires numerical approximations of gradients
    - For a function f at a point θ, gradient can be approximated by looking at $\theta + \epsilon$ and $\theta - \epsilon$
    - Approximation is closer when double sided estimate is used
- If g is the derivative of f:

$$g(\theta) \approx \frac{f(\theta + \epsilon) - f(\theta - \epsilon)}{2\epsilon}$$

- Using the 2 sided difference will give a much better estimate but is more computationally expensive

- The derivative of a function at a point is the limit of the numerical approximation

$$f'(\theta) = \lim_{\epsilon \to 0} \frac{f(\theta + \epsilon) - f(\theta - \epsilon)}{2\epsilon}$$

  - For a non 0 value of ϵ, the error of the approximation is $O(\epsilon^2)$
  - For the single sided numerical approximation, the error is $O(\epsilon)$

- To perform gradient checking on a NN:

  1. Reshape $W^{[1]}, b^{[1]}, ..., W^{[L]}, b^{[L]}$ into a single vector θ
  2. Reshape $dW^{[1]}, db^{[1]}, ..., W^{[L]}, b^{[L]}$ into a single vector $d\theta$
  3. For every i in θ, calculate:

$$d\theta_{approx}[i] = \frac{J(\theta_1, \theta_2, ..., \theta_i + \epsilon) - J(\theta_1, \theta_2, ..., \theta_i - \epsilon)}{2\epsilon}$$

  4. Check if $d\theta_{approx}$ and $d\theta$ are reasonably close to each other

     For $\epsilon = 10^{-7}$:

$$\frac{||d\theta_{approx} - d\theta||_2}{||d\theta_{approx}||_2 + ||d\theta||_2} \approx 10^{-7}$$

- Grad check should be only be used when debugging

  - Calculating $d\theta_{approx}$ is very computationally expensive

- If regularization is used, correct cost function must be used to calculate the gradient

- If dropout is used, J is not well defined and cannot use grad check

  - Cost function J that is optimized by dropout is defined by summing over all subsets of nodes that could be eliminated on each iteration
  - Can implement grad check with a `keep_prob` of 1 before turning on dropout

- Implementation of gradient descent may be correct when W and b are close to 0

  - Can run grad check just after random initialization
  - After training the network for a number of iterations, can run grad check again

2.2 Optimization Algorithms

2.2.1 Mini Batch Gradient Descent

- For gradient descent, vectorization will allow computation over all m training examples

  - If m is very large, then vectorization will still be very slow

- Gradient descent requires the whole training set to be processed for a single step of gradient descent

27

- Data from training set can be split into mini batches

$$X^{\{1\}} = [x^{(1)}, x^{(2)}, ..., x^{(1000)}]$$

$$Y^{\{1\}} = [y^{(1)}, y^{(2)}, ..., y^{(1000)}]$$

- Mini batch gradient descent looks at one mini batch on each iteration of gradient descent

- For each mini batch in the training set:

  - Run forward propagation on $X^{\{t\}}$

    $$Z^{[1]} = W^{[1]} X^{\{t\}} + b^{[1]}$$

    $$A^{[1]} = g^{[1]}(Z^{[1]})$$

    ...

    $$A^{[l]} = g^{[l]}(Z^{[l]})$$

  - Compute cost: $J^{\{t\}} = \frac{1}{1000} \sum_{i=1}^{l} \mathcal{L}(\hat{y}^{(i)}, y^{(i)}) + \frac{\lambda}{2 \times 1000} \sum_{l} ||W^{[l]}||_F^2$

  - Use backpropagation to calculate gradients wrt $J^{\{t\}}$

  - Update weights

    $$W^{[l]} := W^{[l]} - \alpha dW^{[l]}$$

    $$b^{[l]} := b^{[l]} - \alpha db^{[l]}$$

- A single pass through the training set is known as an epoch

- Algorithm can continue to run for multiple passes through the training set until an optimal solution is found

- For batch gradient descent, the cost should decrease on each iteration

  - If the cost doesn't decrease per iteration, then the algorithm has a bug

- For mini batch gradient descent, the cost will trend downwards but will be more noisy

  - Algorithm is being trained on a different batch of results on each iteration

- When running mini batch gradient descent, must choose the size of the mini batch

  - For mini batch size $= m$: Batch gradient descent

  - For mini batch size $= 1$: Stochastic gradient descent

- For stochastic gradient descent, each example may be good or bad for gradient descent

  - On average the cost function will be minimized for gradient descent

  - Path taken by gradient descent will be very noisy

- Stochastic gradient descent will never converge and just oscillate around the minimum

- Choice of mini batch size should be between 1 and m
  - Batch gradient descent will take very long for a single iteration
  - Stochastic gradient descent will lose all the speed from vectorization
- For a small training set ($m \leq 2000$), can just use gradient descent
- Otherwise can try a mini batch size from 64-512
  - Code may run faster if the mini batch size is a power of 2
- A single mini batch should be able to fit in the whole CPU/GPU memory

Advanced Optimization Algorithms
- Some advanced algorithms require the use of exponentially weighted averages
- Moving averages can be calculated for data such as daily temperature

$$V_0 = 0$$

$$V_t = \beta V_{t-1} + (1 - \beta)\theta_t$$

  - V_t is the approximated average temperature over the last $\frac{1}{1-\beta}$ days
  - If β is larger then the average will adapt slower to changes in the data
- Exponentially weighted average can be found by summing the daily temperature with an exponentially decaying function
- If $\beta = 0.9$:

$$V_{100} = 0.1\theta_{100} + (0.1)(0.9)\theta_{99} + (0.1)(0.9)^2\theta_{98} + (0.1)(0.9)^3\theta_{97} + ...$$

- When calculating the exponentially weighted average, the same variable v should be used and overwritten each time
  - Implementation will be much more efficient than calculating average manually from the past 10 values
- For large values of β, initial average will be much lower than they should be

$$\frac{V_t}{1 - \beta^t}$$

- Bias correction can be used to ensure initial values are correct estimations of the averages
  - As t becomes larger, denominator becomes closer to 1

Momentum

- Gradient descent with momentum uses an exponentially weighted average of the gradients to update the weights

    - Almost always performs better than standard gradient descent

    $V_{dW} = \beta V_{dW} + (1 - \beta)dW$

    $V_{db} = \beta V_{db} + (1 - \beta)db$

    $W = W - \alpha V_{dw}$

    $b = b - \alpha V_{db}$

- Taking the average of the gradients will slow down any unnecessary oscillations in the algorithm

    - Algorithm may oscillate at first but will start to take more direct steps to the minimum

- $\beta = 0.9$ is a common choice for most applications of momentum

RMSprop

- RMSprop takes the weighted average of the squares of the derivatives

- Derivatives will get divided by the RMS before the weights are updated

    $S_{dW} = \beta_2 S_{dW} + (1 - \beta)dW^2$

    $S_{db} = \beta_2 S_{db} + (1 - \beta)db^2$

    $W = W - \alpha \frac{dW}{\sqrt{S_{dw}}}$

    $b = b - \alpha \frac{db}{\sqrt{S_{db}}}$

- Updates in the direction of oscillation will be divided by a large number

    - Will allow the learning rate to be larger and therefore allows faster training

- In practice, very small value ϵ is added to the denominator for more numerical stability

Adam Optimization Algorithm

- Adam optimization shown to work well for a range of deep learning architectures

    - Merges Momentum and RMSprop to one algorithm

    - "Adam" stands for adaptive moment estimation

- On iteration t:

    Compute dW, db using the current mini batch

$$V_{dw} = \beta_1 V_{dw} + (1 - \beta_1)dW, \quad V_{db} = \beta_1 V_{db} + (1 - \beta_1)db$$

$$S_{dw} = \beta_2 S_{dw} + (1 - \beta_2)dW^2, \quad S_{db} = \beta_2 sdb + (1 - \beta_2)db^2$$

$$V_{dw}^C = \frac{V_{dw}}{1 - \beta_1^t}, \quad V_{db}^C = \frac{V_{db}}{1 - \beta_1^t}$$

$$S_{dw}^C = \frac{S_{dw}}{1 - \beta_2^t}, \quad S_{db}^C = \frac{S_{db}}{1 - \beta_2^t}$$

$$W := W - \alpha \frac{V_{dw}^C}{\sqrt{S_{dw}^C} + \epsilon}$$

$$b := b - \alpha \frac{V_{db}^C}{\sqrt{S_{db}^C} + \epsilon}$$

- Must choose many hyperparameters to run Adam optimization
  - α: needs to be tuned to the specific NN
  - β_1: 0.9 (default)
  - β_2: 0.999 (default)
  - $\epsilon : 10^{-8}$ (default)

Learning Rate Decay

- For mini batch gradient descent, the algorithm will oscillate around the minimum point
- If the learning rate is reduced over time, then the oscillations will become smaller
  - During the initial steps of learning, algorithm can afford to take large steps
 - As the algorithm starts to converge, smaller steps are preferred

$$\alpha = \frac{1}{1 + \text{decay rate} \times \text{epoch num}} \alpha_0$$

- Other formulas can be used to decay the learning rate
  - Exponential decay

$$\alpha = 0.95^{\text{epoch num}} \alpha_0$$

  - Discrete staircase

31

– Square root of epoch number

$$\alpha = \frac{k}{\sqrt{\text{epoch num}}}\alpha_0$$

- Manual decay can be used for larger models that take a longer time to train

Local Optima

- Initial ideas believed that a cost function with many points of 0 gradient would have many local optima
  - When training a NN, most points with 0 gradient are saddle points
- For a point with 0 gradient, Each direction can either be a convex or concave function
  - For a local optima, must have a convex function in all directions
  - In a high dimensional space, chance of all directions being convex functions is very small
- Intuitions about lower dimensional spaces may not transfer to high dimensional spaces
- Plateaus are areas where the gradient is near to 0 for a large area
  - Will take a very long time to move down off the plateau

– Learning will be slow but unlikely to get stuck in a local optima

• Optimization algorithms like Adam can help to speed up the training

2.3 Hyperparameter Tuning, Batch Normalization and Programming Frameworks

2.3.1 Hyperparameter Tuning

• Deep neural networks have many hyperparameters associated with the actual network and the training implementation

  – Numbers of layers and hidden units

  – Learning rate or method for learning rate decay

  – Hyperparameters for momentum or Adam optimization

  – Mini batch size

• Most important hyperparameter is the learning rate

  – Secondary importance can be given to momentum (β), number of hidden units and the mini batch size

  – Number of layers and learning rate decay can be tuned last

  – Parameters for Adam optimization usually don't need to be tuned

• In practice, random values for the hyperparameters should be sampled and tested

  – If values are arranged in a grid, fewer distinct values can be tested

  – Choosing random values for the hyperparameters gives a higher chance of finding an optimum value for important hyperparameters

• Can use coarse to fine sampling scheme to find optimum values

  – Sample initial values and find which values work the best

  – "Zoom in" to the area and take more samples in the smaller region

• For some hyperparameters (number of layers / hidden units), can sample over a reasonable range

• Some hyperparameters may not have an even distribution (Learning rate between 0.0001 and 1)

  – Can use a log scale to ensure the numbers are better distributed

```
r = -4 * np.random.rand
learning_rate = 10 ** r
```

- Can look for a range $10^a...10^b$ and take a random sample $r \in [a, b]$

- For exponentially weighted averages, β will be around 0.9-0.999

  - Equivalent to averaging over the last 10 days or last 1000 days

  - Can sample values for $1 - \beta$ for $r \in [-3, -1]$

- For exponentially weighted averages, the sensitivity of the results is very high when β is close to 1

  - A change from 0.999 to 0.9995 will change the average from 1000 to 2000 examples

- Intuitions about the hyperparameters won't always transfer across applications

  - Ideas found in one application can still be applied to other applications

- Hyperparameters can become stale over time with changing data or hardware

  - Hyperparameters should be reevaluated every few months to ensure values are optimal

- Depending on resources, can babysit a single model or train models in parallel

  - For a single model, hyperparameters can be tweaked over time depending on training performance

  - If resources allow, can train the same model with many different hyperparameters and choose the best model

2.3.2 Batch Normalization

- Inputs to a NN can be normalized to speed up learning

$$X = \frac{X - \mu}{\sigma}$$

- Batch normalization normalizes the input values $Z^{[l]}$ to each layer

  - Can instead normalize the values $A^{[l]}$ after the activation function

- Given intermediate values $z^{(1)}, ..., z^{(m)}$:

  $\mu = \frac{1}{m} \sum_i z^{(i)}$

  $\sigma^2 = \frac{1}{m} \sum_i (z^{(i)} - \mu)^2$

  $z_{norm}^{(i)} = \frac{z^{(i)} - \mu}{\sqrt{\sigma^2 + \epsilon}}$

  $\tilde{z}^{(i)} = \gamma \, z_{norm}^{(i)} + \beta$

- γ and β are learnable parameters of the model

  - Allows the mean and variance of $\tilde{z}$ to be set to any value

- If $\gamma = \sqrt{\sigma^2 + \epsilon}$, $\beta = \mu$, then $\tilde{z}^{(i)} = z^{(i)}$

- May not want mean 0 and standard deviation 1 for the activation function

- NN will have new parameters $\beta^{[1]}, \gamma^{[1]}, ..., \beta^{[L]}, \gamma^{[L]}$

  - Will be updated like normal parameters

$$\beta^{[l]} = \beta^{[l]} - \alpha d\beta^{[l]}$$

$$\gamma^{[l]} = \gamma^{[l]} - \alpha d\gamma^{[l]}$$

- Batch normalization is typically applied to mini batch gradient descent

  - Mean and variance will be calculated from the mini batch being used

- When using batch normalization, normalization step removes the need for $b^{[l]}$ parameters

  - When subtracting the mean from the z values, the constant will get cancelled out

  - Mean of the $\tilde{Z}$ values will be decided by the $\beta^{[l]}$ parameters

- Batch normalization will make weights deeper in a network more robust to changes earlier in the network

  - Data can have a covariate shift where the distribution changes after a generalization

  - Function mapping from X to Y can be the same but model may need to be retrained

  - Batch normalization will reduce the amount of movement of the distribution of the hidden values

- Even if there is a covariate shift in the data, batch norm will make the z values have the same mean and variance

  - The individual layers in the network will be more independent of each other

- Batch norm will also add a slight regularization effect

  - Each mini batch is scaled by the mean/variance of the specific mini batch

  - Normalizing with the mean/variance of the individual mini batch will add noise to the activations

  - Similar to dropout where the algorithm will not rely on any single hidden unit

  - Noise added to the z values is very small so dropout can be used as well

- If a larger mini batch size is used, noise is reduced and will have a smaller regularization effect

- At test time, data will typically be processed one example at a time

- – Cannot calculated the mean/variance of a single example

- – Mean/variance can be estimated using exponentially weighted averages across the mini batches

2.3.3 Multi Class Classification

- Logistic regression can be generalized to apply to multiple classes

$$C = \text{number of classes}$$

- Output layer for the NN will have C units
    - – Each unit will be the probability of each class
    - – Sum of all numbers in the vector must be 1

- Softmax layer used in the output layer to output vector of probabilities
    - – $Z^{[L]}$ values are calculated as normal: $Z^{[L]} = W^{[L]}a^{[L-1]} + b^{[L]}$
    - – Use the softmax activation function

        $t = e^{(Z^{[L]})}$

        $a^{[L]} = \frac{t}{\sum_{i=1}^{C} t_i}$

- Softmax activation function has a vector for its input and output
    - – Other activation functions had a single value for input and output

- Largest input to softmax function will result in the largest output
    - – "Hard max" function would return 1 for the largest input and 0 for the other inputs

- If $C = 2$, softmax reduces to logistic regression

- Softmax classifier cannot be trained as a normal NN

$$\mathcal{L}(\hat{y}, y) = -\sum_{j=1}^{C} y_j \log \hat{y}_j$$

- Loss function will only be active for the ground truth class in the training set

$$J(W^{[1]}, b^{[1]}, ...) = \frac{1}{m} \sum_{i=1}^{m} \mathcal{L}(\hat{y}^{(i)}, y^{(i)})$$

$$dz^{[L]} = \hat{y} - y$$

36

2.3.4 Deep Learning Frameworks

- For larger NNs, using a framework can save a lot of time
- Can look at the community behind the frameworks and the strengths
  - Ease of programming (development and deployment)
  - Running speed
  - Truly open (open source with good governance)
  - Application of NN

Tensorflow

- Assume a simple cost function:

$$J(w) = w^2 + 10w + 25$$

```python
import numpy as np
import tensorflow as tf

w = tf.Variable(0, dtype=tf.float32)
optimizer = tf.keras.optimizers.Adam(0.1)

def train_step():
    with tf.GradientTape() as tape():
        cost = w ** 2 - 10 * w + 25
    trainable_variables = [w]
    grads = tape.gradient(cost, trainable_variables)
    optimizer.apply_gradients(zip(grads, trainable_variables))

for i in range(1000):
    train_step()
```

- No need to compute backpropagation steps with tensorflow
- More complex tensorflow program will have cost as a function of variables

```python
w = tf.Variable(0, dtype=tf.float32)
x = np.array([1.0, -10.0, 25.0], dtype=np.float32)
optimizer = tf.keras.optmizers.Adam(0.1)
```

```python
def training(x, w, optimizer):
    def cost_fn():
        return x[0] * w ** 2 + x[1] * w + x[2]

    for i in range(1000):
        optimizer.minimize(cost_fn, [w])

    return w
```

- Tensorflow will create a computation graph from the defined cost function
  - From the computation graph, tensorflow will compute the backpropagation steps

3 Structuring Machine Learning Projects

3.1 ML Strategy

3.1.1 Setting up a ML Project

- A machine learning project may have many ideas that can improve performance
    - Collect more data
    - Use a more diverse training set
    - Train the algorithm over a longer period of time
    - Use a different optimization algorithm (Adam instead of gradient descent)
    - Use a bigger/smaller network
    - Add dropout or L_2 regularization
    - Change the network architecture (activation functions or hidden units)
- Some methods may not be useful for the specific scenario
- ML strategy is changing with deep learning
    - Deep learning algorithms have different options when compared with previous generations
- Orthogonalization is where specific functions can be split up into different areas
- For a supervised learning system to perform well, system requires a chain of assumptions
    - Performance of algorithm on the training set must pass some threshold ($\approx$ human-level performance)
    - Algorithm must be fit well to the dev set
    - Algorithm must be fit well to the test set
    - Algorithm must perform well in the real world
- Each step has specific "knobs" to tune to improve performance in the specific area
    - Training set: bigger network, Adam optimization
    - Dev set: regularization, bigger training set
    - Test set: bigger dev set
    - Real world: change dev set or cost function
- Early stopping can be used but is less orthogonalized
    - Worsens the performance on the training set

- Improves the performance on the dev set

- Single number evaluation metric can be used to test effectiveness of a model

- F1 score combines precision and recall into a single metric

  - Precision is the percentage of positively classified examples that are actually positive

  - Recall is the percentage of positive examples that are correctly classified

  - F1 score takes the harmonic mean of precision and recall

$$F_1 = \frac{2}{\frac{1}{P} + \frac{1}{R}}$$

- Having a well defined test set and single number evaluation metric will speed up iteration

- Scenario may have more than one type of metric that is relevant

  - Classification algorithm may value accuracy as well as running time

  - May not make sense to use a numerical function of some metrics

- Accuracy would be a optimizing metric and running time would be the satisficing metric

  - Goal can be to maximize accuracy subject to running time $\leq$ 100ms

- For N different metrics:

  - 1 should be optimizing

  - $N - 1$ should be satisficing

- Dev set and test set should come from the same distribution

  - If different distributions are used, algorithm may perform on the dev set but not on the test set

  - Dev set and test set must have the same target

- Dev set should be used to evaluate the performance of different models

  - Setting up a dev set and an evaluation metric allows teams to iterate quickly

  "Choose a dev set and test set to reflect data you expect to get in the future and consider important to do well on"

- Previous eras of machine learning had a 60%, 20%, 20%

- Modern eras of machine learning have much larger datasets

  - For 1000000 examples, can assign 1% each to dev and test set

– Larger amount of data in the training set will help algorithm

"Set your test set to be big enough to give high confidence in the overall performance of your system"

- Some applications may only use a train and dev set

  – Specific scenario may not require high confidence in the overall performance of the algorithm

  – Must be careful to not overfit the dev set too much

- Evaluation metric may not give a full representation of the specific scenario

  – Cat classifier with very low error may allow some pornographic images through the algorithm

  – Algorithm with slightly higher error but no pornographic images would be preferred

- Evaluation metric should be changed if it doesn't correctly rank the algorithm's performance

  – Standard error function treats all images equally

  – Weight can be added to the error function to weight unwanted images higher

  – Requires labelling of unwanted images in dev and test set

- Task of changing evaluation metric is separate from changing cost function to achieve good performance

- Metric and/or dev/test set should be changed if performance on the application is not linked

3.1.2 Comparing to Human Level Performance

- With advances in deep learning, ML algorithms have much better performance

  – More feasible for algorithms to be competitive with human level performers

- Workflow of designing and building a ML system is more efficient when trying to learn something that humans can do

- For many ML projects, initial learning will be very fast as algorithm approaches human level performance

  – Rate of learning decreases after algorithm surpasses human level performance

  – Algorithm will approach Bayes optimal error

- Bayes optimal error is the best theoretical function for mapping from X to Y

  – For many tasks, human level performance is not very far from Bayes optimal error

- – Once human level performance is surpassed, there may not be many areas to improve in

- If algorithm has lower than human level performance:

  - – Get labelled data from humans

  - – Gain insight from manual error analysis

  - – Better analysis of bias/variance

- If human level performance is much lower than the training and dev set error, can focus on the bias of the algorithm

- If human level performance is close to the training error, can focus on the variance of the algorithm

- Human level performance can be used as an estimate for Bayes error

  - – Difference between the Bayes error and training error is the avoidable bias

  - – Difference between the training and dev set error can measure the variance

- For specialized tasks, different parties may have different errors for human classification

  - – For medical image classification, a team of experienced doctors will have much lower error than an average human

  - – Bayes error must be less than or equal to the lowest human error

  - – Lowest human error can be used as estimate for Bayes error

- For publishing a paper or deploying a system, human error definition may be different

- When algorithm is very close to human level performance, can be hard to see if bias or variance should be trained

- With deep learning, algorithms in some areas can surpass human level performance

  - – Online advertising

  - – Product recommendations

  - – Logistics

  - – Loan approvals

- Above areas are not natural perception problems and come from structured data

  - – Currently more challenging for computers to surpass humans in natural perception tasks

- ML has also surpassed humans in some natural perception tasks

  - – Speech recognition

  - – Some image recognition

- Medical tasks

- For supervised learning, must assume that the training set can be fit well (low avoidable bias)

  - The training set performance must also generalize well to the dev/test set (low variance)

- For high bias:

  - Train a bigger model

  - Train for longer or use a better optimization algorithm (momentum, RMSprop, Adam)

  - Change the NN architecture or find better hyperparameters

- For high variance:

  - Use more data

  - Use regularization (L_2, dropout, data augmentation)

  - Change the NN architecture or find better hyperparameters

3.1.3 Error Analysis

- Misclassified examples can be manually examined to look for any patterns

  - Finding patterns can give an upper bound of any increase in performance

- Different ideas for error analysis can be evaluated in parallel with a table

  - For each image, can fill in a checkbox for any patterns

  - Percentage of total for each pattern will give an idea of how to best improve performance

- Manual analysis may show new patterns in the errors

- Some errors may be incorrectly labelled examples in the dev/test set

  - Deep learning algorithms are quite robust to random errors in the training set

  - Algorithms are fairly susceptible to systematic errors in the training set

- Incorrectly labelled examples can be recorded in the error analysis table

  - Percentage of error caused by incorrect labels can be calculated to see if fixing labels is a worthwhile task

- Any processes should be applied to the dev and test set at the same time to ensure they come from the same distribution

  - Training set may end up coming from a different distribution than the dev/test set

- Can also look at examples that the algorithm got right to see if got any errors

- For a new ML system, priority should be to build initial system then iterate
  - Set up a dev/test set and evaluation metric
  - Build initial system quickly
  - Use bias/variance and error analysis to prioritize next steps

- Error analysis will give idea for next steps

3.1.4 Mismatched Training and Dev/Test Sets

- Deep learning algorithms perform best with a lot of training data
  - Many teams are putting as much data as possible into training sets
  - Extra data added to the training set will give a different distribution to the training set data

- Other sources of data may have more examples but can come from a slightly different distribution

- Data can be pooled together and randomly split into training, dev and test set
  - All data will come from the same distribution
  - Much of the dev set will come from the additional distribution of images rather than the original distribution
  - Algorithm will optimize to the wrong distribution of images

- Training set can be set to include all images from the additional distribution
  - Examples from the original distribution will be split between the dev and test set
  - Dev and test set will have the correct distribution of images
  - Training set will have a different distribution

- Estimate of bias and variance changes when training set has a different distribution to dev and test set
  - Comparatively high dev set error might mean dev set has more challenging images than training set
  - Data from the dev set will be new to the algorithm and will have a different distribution to the training data

- Portion of the training set can be set as the training-dev set
  - Should not be used for training but will have the same distribution as the training set

- For error analysis, can look at the training set, training-dev set and dev set

44

- Large difference between the training error and training-dev error indicates a variance problem

- Large difference between the training-dev error and dev error indicates a data mismatch problem

- Large difference between training error and human error indicates high bias problem

- Difference between the dev error and test error indicates degree of overfitting to the dev set

- For each distribution of data, can look at:

  - Human level error

  - Error on examples trained on

  - Error on examples not trained on

- For data mismatch:

  - Use manual data analysis to try understand the difference between training and dev sets

  - Can try to make the training set more similar to the dev set (collect more examples or use artificial data synthesis)

- For some applications, algorithm may overfit during artificial data synthesis

  - For speech recognition, same recording of noise may be added to many examples

  - As much as possible, should aim to get a large range of examples with data synthesis

3.1.5 Learning From Multiple Tasks

- For some applications, NN trained for one task can be applied to another task

  - NN trained for cat recognition can be retrained for radiology diagnosis

- After initial NN is trained, output layer should be deleted

  - Weights for the output layer should be randomly initialized

  - Dataset can be switched to new application and NN retrained

- If the new dataset is small, can just retrain the last layer of the NN

  - If there is a lot of data, all layers in the NN can be retrained

  - Pre-training is the training of the NN for the original application

- Learning basic feature of images from a large dataset can help performance of algorithm

- Transfer learning works best when there is comparatively more data for the initial training
  - Initial training will not be useful if there is more data in the fine-tuning dataset
  - Both tasks must have the same input type
  - Low level features should be helpful for learning B
- For multi task learning, a single NN will try to learn multiple things at a time
  - Each task will ideally help the other tasks
- For self driving vehicles, many objects need to be identified from input data
  - Pedestrians
  - Cars
  - Different types of signs
  - Traffic lights
- Output from NN will be a vector for each object

$$\frac{1}{m}\sum_{i=1}^{m}\sum_{j=1}^{4}\mathcal{L}(\hat{y}_j^{(i)}, y_j^{(i)})$$

  - Output from NN can have all objects in the same image
  - Softmax regression had only one output label for each image
- NN trained to minimize above cost function is using multi task learning
  - Separate NN could have been trained for each object
  - Basic image features for all NN can be shared
- Multi task learning can also be done if the dataset is incomplete
  - Dataset may have missing values for some objects
  - When calculating the cost, missing values can be ignored in the sum
- Multi task learning should have tasks that benefit from having shared lower level features
  - Amount of data for each task tends to be similar
  - Must be able to train a big enough NN to do well on all tasks
- Transfer learning tends to be more common than multi task learning
  - Multi task learning more common in computer vision

3.1.6 End to End Deep Learning

- End to end deep learning takes multiple stages of processing and combines it into a single NN

- For sound recognition:
  - Individual features of the sound (MFCC)
  - Recognizing phonemes
  - Recognizing words
  - Final transcript

- End to end deep learning requires a lot more data than the standard pipeline
  - A medium sized dataset can use a mixture of end to end learning and the standard pipeline

- For an identity detection algorithm using a camera, algorithm will first detect the person's face
  - Algorithm will then crop the image to the face and use the image to identify the person
  - Algorithm will compare new image to all existing images of recognized people

- For each individual step, there is a lot of data for each step
  - Will be a lot harder to find data for both concurrent steps

- End to end deep learning used for machine translation

- Estimating a child's age from an x-ray more suited to different tasks
  - Much easier to identify bones from x-ray before estimating age
  - Possible to use end to end method with a lot of data

- End to end deep learning requires less hand-designing of components
  - Hand-designing components may be constricting the data

- End to end deep learning requires a large amount of data
  - Hand-designed components could be useful when there is comparatively little data

  "Do you have sufficient data to learn a function of the complexity needed to map x to y"
